

NOVEL USES FOR PROTON PUMP INHIBITORS

The present invention provides the use of proton pump inhibitors, such as omeprazole, in antineoplastic therapies.

Existing antineoplastic strategies have shown low levels of efficacy against solid tumours, together with high *in vivo* systemic toxicity, and there remains a need for new antitumour strategies with low systemic toxicity.

Our recent data suggest that tumour malignancy and invasiveness are associated with two main mechanisms: (i) an aberrant phagocytic activity (Lugini *et al.*, 2003); and, (ii) the release of exosomes able to kill lymphocytes through a Fas-mediated apoptotic mechanism (Andreola *et al.*, 2002). It is conceivable that a common mechanism links the two, possibly involving the traffic of strongly acidified vesicles, belonging to a powerful lysosomal network. Inhibition of the actin cytoskeleton connection to the lysosomal membranes may impair these tumour functions.

The influence of pHi (intracellular pH) has been studied with respect to cell growth, cell motility, tumorigenesis, metastasis and apoptosis in cancer cells (Perona *et al.*, 1988; Schlappack *et al.*, 1991; Gottlieb *et al.*, 1995; Helmlinger *et al.*, 1997; Martinez-Zaguilan *et al.*, 1998).

The microenvironment of solid tumours contains regions of poor oxygenation and high acidity. Growing evidence from clinical and experimental studies points to a fundamental role of an acidic tumour microenvironment in metastatic progression (Subarsky and Hill, 2003). Decreased pO₂, acidity, and the lack of nutrients alter gene expression. Genes that play a role in angiogenesis, tissue remodelling, and survival, are necessary for the survival of tumour cells, and play a pivotal role in metastatic progression (Subarsky and Hill, 2003).

The extracellular (interstitial) pH of solid tumours is significantly more acidic than that of normal tissues (Izumi H *et al.*, 2003). Although the data are limited, pH measurements in humans indicate a difference between tumour and normal tissues (Tannock and Rotin 1989). Moreover, acidic intracellular organelles can also participate in resistance to chemotherapeutic drugs (Altan *et al.*, 1998; Hurwitz *et al.*, 1997; Schindler *et al.*, 1996; Larsen *et al.*, 2000; Raghunand *et al.*, 1999; Ouar *et al.*, 1999), thus conferring to tumour cells a cumulative overall

selective advantage.

The acidity displayed by tumours has been proposed as a potentially useful tool to distinguish tumour tissues from healthy ones. Possible tumour functions, in which the acidification of extracellular environment and lysosomal compartments may have a role, include: (i) direct impairment of lymphocyte functions through acidity (Ratner and Heppner, 1985); and, (ii) the raising of a chemical/physical barrier capable to inactivate and/or sequestrate chemotherapeutic drugs (Altan *et al.*, 1998).

It is conceivable that the acidic tumour microenvironment, and the highly efficient tumour lysosomal compartment, of tumour cells, together may represent a sort of digestive apparatus, allowing tumour cells to feed by way of an extracellular matrix on dead cells (Lugini *et al.*, 2003). Thus, it may be that tumour microenvironment acidification presents as an overall selective advantage.

Enhanced expression and activity of Vacuolar type H^+ ATPases (VH^+ ATPases), a class of active H^+ transporters, in tumour cells, may have a key role in the acidification both of the tumour extracellular microenvironment and of the intracellular acidic compartments.

The acidic microenvironment of cancer cells has also been associated with multidrug resistance. Resistance to chemotherapeutic agents is a major cause of treatment failure in patients with cancer, and can be caused by biochemical and/or physiological mechanisms. Biochemical mechanisms include the over-expression of resistance-conferring proteins, such as, for example, P-glycoprotein (P-gp), a plasma-membrane drug efflux transporter. Physiological resistance involves the tumour microenvironment, and can be caused by alterations of intra- and/or extra-cellular pH.

In vitro, low pH reduces the uptake of weakly basic chemotherapeutic drugs and, hence, reduces their cytotoxicity (Raghunand *et al.* 1999). This phenomenon has been postulated to contribute to a 'physiological' resistance to weakly basic drugs *in vivo*, and data obtained in animal models show that bicarbonate-induced extracellular alkalinisation leads to significant improvements in the therapeutic effectiveness of some chemotherapeutic drugs, including doxorubicin, against human tumour cells, both *in vitro* and *in vivo* (Raghunand *et al.* 2003; Mahoney *et al.* 2003). Studies in model systems have demonstrated that tumour pH can be a determinant of treatment response.

Acidic intracellular organelles can also participate in resistance to chemotherapeutic drugs (Altan *et al.*, 1998; Hurwitz *et al.*, 1997; Schindler *et al.*, 1996; Larsen *et al.*, 2000; Raghunand *et al.*, 1999; Ouar *et al.*, 1999). The turnover of acidic vesicles may represent an important factor in chemoresistance, especially in cells that do not over-express plasma membrane bound drug pumps, such as P-glycoprotein. In fact, some data suggest that chemotherapeutic drugs distribute through the cytoplasm and nucleoplasm of drug-sensitive cells, but are excluded from the nucleus in drug-resistant cells (Altan *et al.*, 1998; Hurwitz *et al.*, 1997; Schindler *et al.*, 1996; Larsen *et al.*, 2000; Raghunand *et al.*, 1999; Ouar *et al.*, 1999). Indeed, several reports suggest that increased acidification of lysosomal-type vesicles is causally related to drug resistance and is consistent with the hypothesis that sequestration of drugs in acidic organelles and subsequent extrusion from the cell through the secretory pathway contribute to chemotherapeutic resistance (Schindler *et al.*, 1996; Hurwitz *et al.*, 1997; Cleary *et al.*, 1997; Altan *et al.*, 1998; Raghunand *et al.*, 1999; Ouar *et al.*, 1999; Bour-Dill *et al.*, 2000; Larsen *et al.*, 2000). Moreover, some recent findings indicate that lysosomotropic agents that impair the acidic-pH-dependent accumulation of weak-base chemotherapeutic drugs may reverse anthracycline resistance in MDR cells with an expanded acidic lysosomal compartment (Ouar *et al.*, 2003).

Vacuolar H^+ -ATPases (V- H^+ -ATPases) are a class of transporters involved in the control of pH in many cellular compartments. This family of efflux pumps has a number of functions in eukaryotic organisms, and is diffusely expressed in many cellular types, including some human tumour cells (Beck, 1987; Vaananen *et al.*, 1990; Marquardt *et al.*, 1991; Martinez-Zaguilan, 1993; Moriyama, 1996; Murakami *et al.*, 2001). These ATPases carry out ATP-dependent proton transport from the cytoplasmic compartment to the opposite side of the membrane, that in turn may be represented by either the lumen of an intracellular organelle or the extracellular space.

Proton pump inhibitors (PPIs), including omeprazole and its analogues, such as esomeprazole, lansoprazole, pantoprazole, and rabeprazole, specifically inhibit pumps responsible for the active transport of H^+ ions from cytoplasm across the plasma membrane (to the extracellular space) or across the vacuolar membrane (to the lumen of acidic vesicles). These molecules are drugs currently used to treat the symptoms of peptic disease.

JP 2003277262 discloses a combination of lansoprazole and a mixture of esters for use as an anticancer agent in the gut, wherein the esters increase the bioavailability of

lansoprazole.

JP 2001286284 discloses a peptide sub unit of V-ATPase and antibodies thereagainst having PPI activity. It is speculated that these antibodies may have anticancer activity, as V-ATPase is associated with tumours.

WO 02/080917 discloses the use of proton pump inhibitors for the treatment of induced multi-drug resistance (MDR) in conditions including malaria and cancer. Simultaneous administration of the proton pump inhibitor and anticancer agent is suggested. Induced MDR is associated with characteristic protein expression, such as protein transporters, including the ABC protein transporters. Inherent resistance, which is not associated with such expression, is not addressed, and is a considerably more serious problem in cancer therapy. The authors report that simultaneous treatment with the PPI and a drug, such as doxorubicin or vincristine, apparently led to a small increase in drug sensitivity of the tumour cells.

EP 0567643 discloses a number of novel anti-ulcer agents, and the authors speculate that these agents may also possess anticancer activity, although there are no data to support this.

Surprisingly, we have now found that the proton pump inhibitors, on their own, are able to exert antineoplastic effects on solid tumours, and that they are able to substantially completely restore drug sensitivity to such tumours, where resistance is presented, when used as a pre-treatment.

Thus, in a first aspect, the present invention provides the use of a PPI in the manufacture of a medicament for the treatment of a cancerous condition.

It is preferred that the cancerous, or neoplastic, condition to be treated is a tumour, and it is further preferred that the tumour is either metastatic, or that there is a significant chance that the tumour is or will be metastatic, as diagnosed by a skilled physician, for example.

As noted above, it is particularly metastatic tumours that are associated with acidic conditions, both intra- and extra-cellularly, and it has been found that, surprisingly, omeprazole and other PPIs are able to exert a systemic effect on such tumours.

It is advantageous to be able to assess the pH of a tumour before and after administration of the PPI, as this can assist the skilled physician in determining both the amount and the type of PPI best suited to treat the individual patient. Such monitoring also

provides for the assaying, *in vivo*, of the direct effect of PPI treatment on tumour pH.

Indeed, in the accompanying Examples, we provide the results from *in vitro* experiments using human cell lines derived from tumours of varying histology, and *in vivo* experiments grafting the same tumor cells into Severe Combined Immunodeficiency (SCID) mice (Lozupone *et al.*, 2000; 2003; 2004 in press), and show that: (i) omeprazole is cytotoxic in a dose-dependent manner, for tumour cells cultured in slightly acidic medium; (ii) it is non-toxic for the same tumour cells cultured in buffered medium; (iii) *in vivo* treatment of human-SCID with omeprazole or its analogues was able to markedly reduce tumour growth, and (iv) that pre-treatment with omeprazole was generally able to reverse, often substantially completely, multidrug resistance (MDR).

PPIs display an important chemical feature in that, being weak bases, they accumulate in acidic compartments, and are activated through protonation, exerting their function as proton pump inhibitors. Thus, they normally accumulate in the stomach.

Proton pump inhibitors (PPIs) have emerged as the drug class of choice for treating patients with acid-related diseases, including gastro-oesophageal reflux disease, duodenal and gastric ulcers. These agents inhibit gastric acid secretion by targeting the gastric acid pump (Larsson *et al.*, 1985; Wallmark *et al.*, 1985; Puscas *et al.*, 1999; Horn 2000). PPIs (typically omeprazole, lansoprazole, pantoprazole, and rabeprazole) are substituted 2-pyridyl methylsulphonyl benzimidazoles that share a similar core structure (Horn 2000). These agents are protonable weak bases with pK_a values of ~ 4 and, so, accumulate selectively in acidic spaces with a pH of < 4 . In such an acidic environment, protonation of the pyridine and benzimidazole nitrogens results in the formation of a tetracyclic sulphenamide, which represents the active form of the drug (Horn 2000).

Thus, preferred PPI's are 2-pyridyl methylsulphonyl benzimidazole PPI's, especially omeprazole, lansoprazole, pantoprazole, and rabeprazole.

In one aspect, it is preferred to treat a cancerous condition that is not a gut cancer. In another aspect, it is preferred not to use lansoprazole, especially where the cancerous condition is associated with the gut.

Although tumour cells are able to survive in neutral, buffered media, we have surprisingly found that when PPIs are used to block the pH fluctuations (lower extracellular, lower intra-vacuolar pH and higher cytoplasmic pH) induced by vacuolar-type H^+ -ATPase

expression and activity in tumour cells, these tumours can be controlled and even killed.

It is particularly surprising is that the PPIs are able to exert a systemic effect on tumours, despite being expected to be bound, or sequestered, in the stomach on ingestion. Nevertheless, it is preferred to administer the PPI in conjunction with an antacid, for example, in order that any acidic stomach condition need not reduce the effectiveness of any orally administered PPI. Thus, it is preferred to administer sufficient antacid to the patient to facilitate uptake of the PPI. Such a dose may be any that is readily determined by the skilled physician but may, as a guide, be that amount recommended by the manufacturer for treating acid reflux, for example.

It will be appreciated that where omeprazole, or PPI, are mentioned herein, then either term relates to any PPI useful in the present invention, unless otherwise apparent. Likewise, where reference is had to the term "tumour", this applies equally to any cancerous condition to which the invention applies, unless otherwise indicated, or apparent, and especially one associated with an acidic microenvironment.

The PPI may be administered in any amount effective to exert an antineoplastic effect. In general, this may be in about the same amount as used for the treatment of a stomach ulcer, for example. An acceptable dosage for omeprazole is generally between 20-40 mg/day. This dosage may increase for other analogues – for example, pantoprazole may typically be administered at 40-80 mg/day. However, even overdoses of 560 or 2400 mg/day have shown neither considerable nor stable side effects.

It will be appreciated that the amounts of PPI used may vary with the patient and their condition, as will be apparent to the skilled physician, and may vary typically upwards, especially if the patient has a peptic condition, for example, that is not being treated by an antacid, for instance. The PPI may suitably be administered in conventional form, as provided by the manufacturer, such forms particularly including any suitable for oral administration, including tablets, capsules and lozenges, for example, as well as delayed and sustained release formulations.

It is generally preferred to pre-treat the tumour patient with another antacid, such as calcium carbonate, or antacid drug, such as an H₂-receptor antagonist, for example ranitidine or cimetidine, in order to inhibit acid secretion in the stomach, thereby enhancing the concentration of PPI able to reach the tumour site, and minimising the concentration remaining in the stomach. Thus, treatment with an antacid is effective to increase the delivery of PPI to

the acidic tumour, as the number of only acidic sites in the body is substantially reduced or, at least, the most significant site is temporarily neutralised, or ameliorated.

Treatment may also be by another route, in order to avoid the stomach and the dilution effect that this is likely to have. Any other suitable route is acceptable, and this may include inhalation, eyedrops, pessaries, delayed release tablets, patches, suppositories, catheters and injections, such as i.p., i.m. or i.v. Any such formulation may be made up as desired, and may typically contain any ingredients suitable to the formulation, such as excipients, stabilisers, emulsifiers, flavourings, sterilants and antibacterials.

In general, the PPI drugs appear to be equally effective in treatment of tumours. Particularly preferred are omeprazole, esomeprazole, lansoprazole, pantoprazole, and rabeprazole, with omeprazole being more preferred. Any medicament may contain one or more PPI as the active ingredient.

PPIs have been found to be surprisingly effective in the treatment of tumours that have become, or are, intractable to other drugs. In particular, we have found that tumours that have the MDR phenotype lose their drug resistance, or resistance is significantly diminished, when pretreated with a PPI. Such pretreatment appears to block the acidifying effect of the resistant tumour, which also appears to lift drug the resistance, leaving the tumour exposed to the effect of the drug selected for its treatment. This result was entirely unexpected.

What is especially surprising is that the effect does not appear to be limited to lightly basic drugs, but appears to lift resistance across the spectrum, in all tested drugs, and restores efficacy, regardless of drug type. What also appears to be the case is that contemporaneous treatment, with no prior treatment with PPI, has no effect, or very little useful effect, and that the tumour needs to be pretreated in order to restore sensitivity.

The reason for the lack of efficacy of the PPI when administered simultaneously with another anticancer drug, such as cisplatin, is unclear, but is clearly demonstrated in the accompanying Examples. Pretreatment yields good results, but results with no pretreatment and only concurrent PPI treatment are comparable to the control with no PPI present. Without being restricted by theory, it appears possible that a drug, such as cisplatin, is having the opposite effect from the PPI, and is activating the acidifying ATPase, thereby neutralising the effect of the PPI, if the PPI has not had the opportunity to have an effect. It is also possible that the two drugs are competing for sequestration in the acidic tumour environment, given

that the great majority of anti-cancer drugs are weak bases and that, like the PPI's, require protonation in order to be activated.

Thus, in joint therapy of a cancer, where a PPI is used in conjunction with a second or further anticancer drug, the patient should be pretreated with the PPI, prior to administration of the second or further anticancer drug, which may be a standard cancer treatment. This treatment with PPI may be one, or a series, of treatments, or a continuous treatment, such as by catheter or a transdermal patch, over the previous day or so, by any suitable means, such as oral, systemic or local administration. The length of time is not especially important, provided that the PPI has had a chance to act, and that the effect of the PPI is still present when the other anticancer drug is administered, insofar as the acidic environment is still at least partially compromised at the time of subsequent treatment.

Thus, in a further aspect, the present invention provides the use of a proton pump inhibitor in the manufacture of a medicament for the joint treatment of a cancerous condition, wherein the proton pump inhibitor medicament is for administration prior to the joint therapy.

In such use, it is particularly preferred that the administration be sufficiently prior to the joint therapy as to reduce the acidity associated with the site of the said condition. The period prior to administration of the joint therapy is preferably between 30 minutes and 3 days. Preferably, the PPI is administered on one or more occasions prior to administration of the joint therapy, the first being at least one day prior to therapy, and preferably followed by another between 2 and 12 hours prior to the joint therapy.

A pretreatment period of about 24 hours may be appropriate, but it is preferred that the PPI be administered at least an hour before treatment, and preferably at least two or more hours, in order to allow the maximum effect of the PPI. The treatment need not necessarily be continuous, once started, as it has been found that the PPI effects on tumour acidity last for a small number of days, such as two or three. However, as PPI treatment is safe, it is generally preferred simply to continue the treatment.

The PPI may be administered continuously over the course of the treatment with the other drug, but it is preferred to administer it as part of a regimen, where a treatment with the PPI is given for a period of between, say, 6 and 24 hours before the other drug, followed by administration of the other drug, with the cycle being repeated as appropriate to the drug to which the tumour would otherwise be resistant. Where this would normally be administered

on a daily basis, the PPI may be administered effectively on a continuous basis, or, say, 6 hours before the drug.

Examples of other drugs, against which resistance can be overcome by PPIs, include: those where MDR appears to be related to efflux pump proteins, including; vinka alkaloids, such as vinblastin, vincristine, vinorelbine, and vindesine; taxanes, such as paclitaxel, and docetaxel; anthracyclines, such as doxorubicin, daunorubicin, epirubicin, and idarubicin; anthracenes, such as bisanthrene, and mitoxanthrene; epipodophyllotoxins, such as etoposide, and teniposide; camptothecins, such as topotecan, and irinotecan/sn38; heavy metal oxyanions, such as arsenite, and trivalent antimony; actinomycin d; mitomycin c; methotrexate; trimetrexate; amsacrine; imitinib; and melphalan; and those where MDR appears not to be related with protein-mediated efflux pumps, including 5-fluorouracil (5-fu) and cisplatin.

It will be appreciated that, while the PPI's possess anticancer activity, when used as part of a joint therapy, it is their ability to reduce drug resistance to another anticancer drug that will generally be of importance, although any cumulative anticancer effect can only be of benefit.

Thus, in an alternative aspect, the present invention provides the use of a PPI in the preparation of a medicament for the treatment of a cancerous condition resistant to one or more antineoplastic drugs in a patient having sub-effective levels of a drug to which the condition is resistant. In such a case, a patient may be on a course of drugs for a cancerous condition, and administration of the PPI is timed such as to have an effect on the acidic microenvironment of the tumour when levels of the other anticancer drug have dropped sufficiently to permit the PPI to have such an effect. Given the toxic effects of most anticancer drugs, it is conventional to allow the patient to recuperate between administrations, so that windows of opportunity are readily found and established by those skilled in the art. That PPI's continue to have the desired effect after 2 or 3 days is also of assistance, so that a patient may readily take the appropriate amount of PPI on the day before the next course of anticancer drug.

Thus, in this context, "sub-effective" indicates that the level of drug is not sufficient to prevent the MDR-reducing effect of the PPI at the time of administration, or at a subsequent stage when sufficient PPI is systemically effective. Preferably, the level of drug to which the condition is resistant should be allowed to drop to negligible levels for at least a short period,

during which the PPI is preferably administered and can act.

The present invention is also useful in the treatment of such conditions as AIDS, which can become refractive to highly active antiretroviral therapy (HAART), for example. Again, it is preferred that the PPI be administered at a time sufficiently after the previous administration of HAART that the effect on the disease condition of each therapy does not conflict.

Thus, the present invention further provides use of a PPI in the manufacture of a medicament for the treatment of a drug resistant disease condition, especially where the disease condition is AIDS, and particularly where the resistance is against HAART.

Other potentially drug resistant disease conditions, and their treatments, suitable for treatment in accordance with the present invention, include the anti-inflammatory treatments of some chronic diseases such rheumatoid arthritis, ulcerative colitis, or Crohn's disease, for example. The most suitable is considered to be where the anti-inflammatory treatment is based on the use of corticosteroids, which are known to engender resistance. Thus, the effect of PPI can also improve the compliance of corticosteroid-based treatments, decreasing the drug-related side effects resulting from high dosages or prolonged treatment regimens.

The present invention is also useful in the long term therapy and treatment of cancerous conditions, as well as in the prophylaxis of such conditions. For example, tamoxifen is used both to prevent breast cancer in women thought to be at high risk, as well as in the ongoing treatment of individuals who have overcome breast cancer, in order to prevent a recurrence. In particular, there is evidence that tamoxifen increases intracellular pH.

The risk of developing resistance is increased in individuals subject to ongoing treatment, so that concurrent administration of a PPI, for example with PPI being administered on days when the drug, such as tamoxifen, is not, can help either to prevent resistance from developing, or help to stop resistance hindering ongoing treatment.

Tamoxifen has a high level of systemic toxicity, while the PPI's have been established to be non-toxic, even in overdosage regimens. Thus, in accordance with the present invention, PPI's may either be used as an alternative drug to tamoxifen, or combined with tamoxifen in the prevention of cancer relapses.

Likewise, other forms of hereditary cancer treated on a prophylactic basis are also susceptible to such treatment. An example is colonic polyposis, and other conditions which

environmental factors may encourage.

Accordingly, the present invention further provides the use of a PPI in the manufacture of a medicament for the prophylaxis of a cancerous condition. It is preferred that such prophylaxis be in conjunction with a further drug, and that administration of the PPI and drug be separated in time, preferably by at least 30 minutes. Suitable separation times are as described elsewhere herein in respect of the present invention.

A method for the treatment or prophylaxis of a cancerous condition in a patient in need thereof, comprising administration of a proton pump inhibitor to said patient, the cancerous condition having an acidic microenvironment associated therewith, and wherein the said proton pump inhibitor is administered in an amount sufficient to raise the pH of the said microenvironment.

Thus, prophylaxis of stomach cancer will differ from treatment of an ulcer, in that it must be continued indefinitely. In addition, for other cancerous conditions, the regimen of PPI administered need not be as high as for the treatment of a stomach ulcer, as the effect on the acidic microenvironment of the tumour persists for up to 3 days, or even more, so that an amount of PPI similar to that prescribed for a stomach ulcer may be taken by the patient only every other day, or even only every third day, for example.

The present invention further provides a combined therapy for the treatment or prophylaxis of a disease condition, said combined therapy comprising administration of

- a) a proton pump inhibitor, and
- b) at least one drug, other than a proton pump inhibitor, for the treatment of said condition, to a patient in need thereof, and wherein said proton pump inhibitor is administered to said patient prior to said at least one drug.

Administration of the PPI is preferably at a time sufficiently prior to the second drug to allow the PPI to at least partially neutralise any acidic microenvironment associated with the condition. More preferably, where the second drug is administered as part of an ongoing regimen, said second drug should be at a concentration below that deemed to be effective for the condition. Thus, it is preferred that the second drug not be administered by patch or, if it is, then the patch should be removed to allow levels of drug to drop below the effective.

It will be appreciated that such regimens may be followed in continuing therapy to prevent recurrence of a condition, as well as to treat the condition, and may also be employed

in the prevention of a condition, particularly in high-risk individuals.

While it has not been confirmed, it seems possible that pH alterations in tumours present an overall selective advantage, rendering tumour cells able to survive, block immune response and spread. Drugs able to act through inhibition of proton pumps and, thus, regulate cellular pH, appear to be able to hinder the advantage represented by pH alterations. This advantage may be conferred by the V-H⁺ ATPases and, indeed, we have found that specific inhibitors of these enzymes, including omeprazole, and its analogues lansoprazole, rabeprazole and pantoprazole, have potent anti-tumour activity.

Brief Description of the Drawings

Figure 1: Cytotoxic effect of omeprazole *in vitro*

The figure shows a dose response curve obtained treating human melanoma cells with 4 logarithmic dilution (x axis: 0 µg/ml, 0.01 µg/ml, 0.1 µg/ml, 1 µg/ml, 10 µg/ml) of omeprazole, in buffered (♦, neutral, pH7,2) or not buffered (■, slightly acidic) culture medium. The results clearly showed that omeprazole was cytotoxic in a dose-dependent manner only for tumour cells grown in slightly acidic medium. Figure shows the median results from three independent experiments. Error bars = standard deviation.

Figure 2: Effects of omeprazole on human tumour growth *in vivo*

The figure shows the median results of three representative *in vivo* experiment on CB.17 *scid/scid* mice engrafted with a human melanoma cell line, derived from a primary lesion. Mice engrafted with tumour cells were treated (■), four times as indicated by arrows) or not (♦) with omeprazole by gavage. Tumour weight (mg) is represented as a function of time. To note the straightforward effect of omeprazole in inhibiting tumour growth. Error bars = standard deviation.

Figure 3: Effects of omeprazole on cisplatin resistance

The Figure shows three (A,B,C) representative dose response curves obtained treating human melanoma cells with three logarithmic dilution (as indicated on X-axes) of cisplatin alone (CTR line) or after a 24 hrs pre-treatment with omeprazole (OM line). As a control (DMSO line) cells were treated with cisplatin plus DMSO, being DMSO the medium in which omeprazole was

solubilised in stock solution. The DMSO final concentration was the same resulting from omeprazole treatment of cells, namely 0.0008%. The results clearly showed that omeprazole was able to almost completely restored cell sensitivity to cisplatin (OM line) on human melanoma cells resistant to cisplatin treatment (CTR line).

Figure 4: Effects of omeprazole on 5-Fluorouracil (5-FU) resistance

The Figure shows three representative dose response curves obtained treating human colon adenocarcinoma (A) or melanoma (B, C) cells with five logarithmic dilution (as indicated on the X-axes) of 5-fluorouracil (5-FU) alone (CTR line) or after 24 hrs pre-treatment with omeprazole (OM line). As a control (DMSO line) cells were treated with 5-FU plus DMSO, being DMSO the medium in which omeprazole was solubilised in stock solution. The DMSO final concentration was the same resulting from omeprazole treatment of cells, namely 0.0008%. The results clearly showed that omeprazole was able to almost completely restored cell sensitivity to 5-FU (OM line) on human tumour cell lines resistant to cisplatin treatment (CTR line).

Figure 5: Effects of omeprazole on P-gp expressing multidrug resistant cells

The Figure shows one representative dose response curves obtained treating CEM-VBL100 cell line with five logarithmic dilution (as indicated on X-axes) of vinblastine sulphate (VBL) alone (CTR line) or after 24 hrs pre-treatment with omeprazole (OM line). As a control (DMSO line) cells were treated with VBL plus DMSO, being DMSO the medium in which omeprazole was solubilised in stock solution. The DMSO final concentration was the same resulting from omeprazole treatment of cells, namely 0.0008%. The results clearly showed that omeprazole was able to almost completely restored cell sensitivity to VBL (OM line) on human tumour cell lines resistant to cisplatin treatment (CTR line).

Figure 6: *In vivo* effects of omeprazole on tumour growth in the human/SCID mouse model

SCID mice were engrafted with a melanoma cell line via s.c. injection into the right flank. At the tumour appearance, mice were left untreated (CTR line) or were treated with omeprazole (1 single gavage treatment at day 1, heavy, down arrow) and cisplatin (1 single i.p. treatment at day 2, lighter, up arrow) OM-CPL line or cisplatin alone (CPL line). Graphs represent tumour growth expressed as mg weight (see Materials and Methods) as a function of time. Results clearly showed

that omeprazole strongly enhanced tumour sensitivity to cisplatin (OM-CPL line), that was almost ineffective if administered alone (CPL line).

Figure 7: Treatment strategies

(A) Dose response curve to three logarithmic dilutions of cisplatin administered contemporary (om/cpl) or after (om+cpl) omeprazole treatment of a representative human melanoma cell line derived from a primary lesion. The results (mean from three independent experiments) showed that only pre-treatment of melanoma cells with omeprazole was able to revert cisplatin resistance. The graph shows the percentage of dead cells in function of drug concentration (X axis: 0 μ M, 0,5 μ M, 5 μ M, 50 μ M). Error bars = standard deviation.

(B) The Figure shows the mean results of three representative *in vivo* experiment on CB.17 *scid/scid* mice engrafted with a human melanoma cell line, derived from a primary lesion. Mice engrafted with tumour cells were treated with cisplatin alone (cpl), after omeprazole pre-treatment (om+cpl line), at the same time of omeprazole treatment (om/cpl line), or left untreated (ctr). Tumour weight (mg) is represented as a function of time. The straightforward effect of omeprazole pre-treatment in reverting cisplatin resistance of human melanoma cells engrafted in SCID mice is noteworthy, while cisplatin/omeprazole contemporaneous treatment did not induce any inhibition drug resistance. Error bars = standard deviation.

The present invention will now be further illustrated with respect to the accompanying, non-limiting Examples.

EXAMPLE 1

IN VITRO EXPERIMENTS WITH OMEPRAZOLE

MATERIALS AND METHODS

***In vitro* Experiments**

Drugs: Omeprazole (Astra-Zeneca), esomeprazole (Astra-Zeneca), pantoprazole (Sigma Tau), lansoprazole (Pharmacia, Sweden) and rabeprazole (Janssen) sodium salts were

resuspended at 1 mg/ml in PBS1X as a stock solution and stored at -20°C.

Tumour cells: Human tumour cells (24 melanoma cell lines, 2 colon adenocarcinoma cell lines and 2 breast cancer cell lines) obtained from a primary tumour were cultured in buffered (with bicarbonate) or not buffered (without bicarbonate) RPMI 1640 medium enriched with 10% foetal bovine serum and antibiotics in a humidified 5% CO₂ and 95% air atmosphere. Tumour cells were kindly supplied by Istituto Nazionale per la cura dei Tumori, Milan, Italy.

Dose response curves: Tumour cells, growing in suspension, were plated at 1.5×10^5 /ml, in 24 wells cell culture plate (Costar). Tumour cells growing in adherence were plated at 3×10^4 cells/well in 24 wells cell culture plate. Each drug was tested for cytotoxicity on each cell type using 4 logarithmic dilutions, as shown in the Figures. Each dilution was tested at least in triplicate in each experiment.

Cytotoxicity assay: Cytotoxicity was evaluated using the Trypan blue exclusion method after treatment with each chemotherapeutic drug. Briefly, after treatment, cells growing in suspension were collected, centrifuged and resuspended in PBS1X. Alternatively, cells growing in adherence were collected, pooling both adherent (live) after trypsinisation and in suspension (assumed dead) cells. Cells were thus centrifuged (10 minutes at 1500 rpm) and resuspended in PBS1X. An aliquot of the cell suspension was diluted 1:1 (v/v) with 0.4% trypan blue. After 5 minutes, cells were loaded on a haemocytometer (Neubauer) and both live (not stained) and dead (blue stained) cells were counted under a light microscope. Cell viability was assessed calculating the percentage of dead cells using the formula:

$$\% \text{ dead cells} = (\text{no. dead cells} / (\text{no. dead cells} + \text{no. live cells})) \times 100.$$

Live/Dead Viability/Cytotoxicity Assay ®. This assay (Molecular Probes, OR, USA) provides a two colour fluorescence cell viability assay that is based on the simultaneous determination of live and dead cells with two probes (Calcein AM and Ethidium homodimer 1) that measure two recognised parameters of cell viability - intracellular esterase activity and plasma membrane integrity. Live cells were distinguished by the presence of ubiquitous intracellular esterase activity, determined by the enzymatic conversion of the virtually non-fluorescent cell permeant Calcein AM to the intensely fluorescent calcein (ex/em 495nm/515nm), which is retained in the cell. Conversely, Ethidium homodimer 1 (EthD-1) enters damaged membranes and undergoes a 40-fold

enhancement of fluorescence upon binding to nucleic acids, thereby producing a bright red fluorescence in dead cells (ex/em 495nm/595nm). EthD-1 is excluded by the intact plasma membrane of live cells. According to the manufacturer's instructions, the optimal dye concentrations for the cell types used in this study were determined, in order to achieve a distinct labelling of dead and live cells, thus permitting an accurate quantitation of cytotoxic effects. After treatment, cells growing in suspensions were collected, centrifuged, and resuspended in PBS1X. Alternatively, cells growing in adherence were collected pooling both adherent (live) after trypsinisation and in suspension (presumably dead) cells. Cells were thus centrifuged (10 minutes at 1500 rpm) and resuspended in PBS1X. Cells were thus treated with Calcein AM and EthD -1 at the final concentration of 0,1 μ M and 1 μ M, respectively, and left at room temperature for 30 minutes. After this incubation period, cells were washed once in PBS 1X and resuspended again in PBS1X. The samples were analysed with a FACScan cytometer (Becton Dickinson) equipped with a 488 argon laser. At least 20,000 events were acquired. Data were recorded and statistically analysed by a Macintosh computer using CellQuest Software. Calculation of fluorescence (expressed as median value) was carried out after conversion of logarithmically amplified signals into values on a linear scale and the statistical significance was calculated by using the parametric Kolmogorov-Smirnov (K/S) test. Statistical analysis of apoptosis data was performed using Student's *t*-test. All data reported are the mean of at least 4 separate experiments \pm standard deviation (S.D.). Only *p* values of less than 0.01 were considered as significant. The resulting bivariate frequency distribution showed the clear separation between the green fluorescent (530 nm) live cell population and the red fluorescent (585 nm) dead-cell population (whenever present).

Statistical analysis: Statistical comparisons were carried out using Student's *t*-test for unpaired two-tailed comparisons. A *p* value of less than 0.05 was considered significant.

RESULTS

Omeprazole is cytotoxic for tumour cells *in vitro*

The aim of the first of the experiments was to establish whether inhibition of VH^+ ATPases through treatment with omeprazole and the other PPIs would be cytotoxic for tumour cells. The cytotoxic effect of omeprazole was tested on 24 human melanoma, 2 human colon

adenocarcinoma and 2 human breast cancer cell lines deriving from primary lesions. These cells were all able to grow, without any affects on cell cycle or viability, in slightly acidic culture medium, represented by RPMI 1640 medium not supplemented with bicarbonate. This was tested, as previous data had shown that the tumour microenvironment is slightly acidic by comparison with respect to normal tissues.

In order to verify that tumour cells are susceptible to omeprazole, we used experimental conditions represented by cells grown in slightly acidic media, on which we performed an omeprazole dose response curve. As a control, the same experiment was performed culturing cells in buffered medium (pH 7.2). In Figure 1, the results on one representative human melanoma cell line are shown. A dose response curve of omeprazole was obtained treating cells with five logarithmic dilutions of the drug in buffered neutral or non buffered acidic medium (Figure 1). The results showed that: (i) omeprazole alone exhibited no apparent cytotoxic effect on the cells tested in neutral pH medium but (ii) the presence of omeprazole in the acidic medium markedly exerted a cytotoxic effect on tumour cells, in a dose-dependent manner. The experiments performed on other tumour cell lines and using the other PPIs gave comparable results (data not shown). The results were fully verified by the Live/Dead viability/cytotoxicity assay.

EXAMPLE 2

IN VIVO EXPERIMENT WITH OMEPRAZOLE

MATERIALS AND METHODS

In vivo

Animals: CB.17 SCID/SCID female mice (Harlan, Italy) were used at 4-5 weeks of age and were kept under specific pathogen-free conditions. SCID mice were housed in microisolator cages, and all food, water and bedding were autoclaved prior to use.

Tumour cells: Human tumour cells (melanoma, colon adenocarcinoma) obtained from both primary lesions were cultured in RPMI 1640 supplemented with 10% FCS, in humidified 5% CO₂ and 95% air atmosphere.

Transplantation and growth of human tumours in SCID mice: Each mouse was injected subcutaneously (s.c.) into the right flank with 3×10^6 cells resuspended in 0.2 ml RPMI 1640 supplemented with 10% FCS. After transplantation, the size of each tumour was measured using callipers. The tumour weight was estimated according to Geran *et al.* (1972) using the formula:

$$\text{Tumour weight (mg)} = \text{length (mm)} \times \text{width}^2 \text{ (mm)} / 2.$$

Mice treatment: Omeprazole (Astra-Zeneca, Italy) and pantoprazole (Sigma Tau) were administered at a dose of 75 mg/kg by gavage as previously described (Watson and Smith, 2001), as a suspension in PBS1X. Lansoprazole (Pharmacia, Sweden) and rabeprazole (Janssen) were administered at a dose of 25 mg/kg by gavage as previously described (Watson and Smith, 2001), as a suspension in PBS1X.

Other: unless otherwise specified, other parameters are as set out in Example 1, above.

RESULTS

The effects of Omeprazole on human tumours growth as assessed *in vivo* in SCID mice engrafted with human tumour cells.

The *in vitro* experiments of Example 1 showed a straightforward cytotoxic effect of omeprazole on human tumour cell lines under slightly acidic conditions. Thus, efficacy was next tested in *in vivo* systems.

To this end, we tested the effects of omeprazole and its analogues on a human/mouse model system represented by CB.17 *scid/scid* mice engrafted by subcutaneous (s.c.) injection with human melanoma cells. This model has proven useful to test *in vivo* the efficacy of various anti-tumour therapies against human tumours, using either local or systemic treatment strategies (Lozupone *et al.*, 2000, 2003, 2004 in press). Mice engrafted with human tumour cells were treated with omeprazole by gavage. The effects of the treatments were measured in terms of tumour growth at different time points. The results showed that repeated omeprazole treatments markedly reduced tumour growth (Figure 2). The results obtained treating mice with omeprazole analogues are fully comparable to that shown with omeprazole (not shown). Notably, histological examination of the human tumours after the experiments were stopped showed that, in the tumours from the omeprazole-treated mice, the tumour mass was occupied by a huge necrotic area that

mostly accounted for the tumour size (not shown), suggesting that the cytotoxic effect was considerably greater than that quantified by the *in vivo* tumour size measurements.

EXAMPLE 3

IN VITRO DRUGS AND PPIs

MATERIALS AND METHODS

In vitro experiments

Drugs: The PPIs were as in Example 1, above. Cisplatin (Aventis, France) was resuspended in PBS1X at a stock concentration of 1 mg/ml, and stored at -20°C . Both stock solutions were thawed immediately before use and not frozen again. 5-Fluorouracil (Teva Pharma, Holland) was supplied in the form of a solution at a concentration of 50 mg/ml, and was stored at r.t. as indicated by the supplier. Vinblastine sulphate (Eli Lilly, Paris, France) was resuspended in a solution of EtOH/Distilled water 1:1000, at a concentration of 0,1 mg/ml, thus obtaining a stock solution stored at 4°C and used in 3 days after resuspension.

Tumour cells: Human tumour cells were as in Example 1, above.

The MDR variant (CEM-VBL100) of CCRF-CEM (CEM) cells were obtained by exposing the parental drug-sensitive human T-lymphoblastoma cell line to increasing sublethal concentrations of vinblastine sulphate (VBL) up to 100 ng/mL (Eli Lilly, Paris, France). All the cells used in this study were cultured in RPMI 1640 medium enriched with 10% foetal bovine serum and antibiotics (basic medium, BM) in a humidified 5% CO_2 and 95% air atmosphere.

The MDR variant (MCF7/DX) of MCF7 was obtained by exposing the parental drug-sensitive human T-lymphoblastoma cell line to increasing sublethal concentrations of doxorubicin (DX) up to 200 ng/mL (Pharmacia & Upjohn, Italy).

Dose response curves: Tumour cells growing in suspension were plated at 1.5×10^5 /ml, in 24 wells cell culture plate (Costar). Tumour cells growing in adherence were plated at 3×10^4 cells/well in 24 wells cell culture plate. Each drug was tested for cytotoxicity on each cell type using 3 to 5 logarithmic dilutions, as shown in the Figures. Each dilution was tested

at least in triplicate in each experiment.

Other: unless otherwise specified, other parameters are as set out in Example 1, above.

RESULTS

Omeprazole enhanced susceptibility of human tumour cells to cisplatin

The aim of the first of experiments was to verify that the inhibition of VH^+ ATPases through treatment with omeprazole and the other PPIs could reverse multidrug resistance of tumour cells. Cisplatin, having the chemical characteristics of a weak base, due to the presence of two amine groups in its molecule, was selected to test the activity of omeprazole as a revertant of weak basic drugs resistance of tumour cells. It had been previously shown that cisplatin resistant tumour cells display higher cellular pH (and lower extra-cellular pH), together with an enhanced expression of vacuolar proton pump genes (Murakami *et al.*, 2002). The effect of omeprazole on cellular resistance to cisplatin was tested on 24 human melanoma, 2 colon-human adenocarcinoma and 2 breast cancer cell lines deriving from primary lesions, and selected for their resistance to cisplatin. In Figure 3, the results on three representative melanoma cell lines are shown. A dose response curve for cisplatin was obtained by treating cells with three logarithmic dilutions of the drug alone, or in the presence of omeprazole. The results showed that: (i) omeprazole alone did not exhibit any cytotoxic effect on the cells tested, under these conditions, and (ii) the presence of omeprazole in the culture medium markedly enhanced susceptibility to cisplatin in all the human melanoma cells tested. The experiments performed on the other tumour cell lines and using the other PPIs gave comparable results (data not shown).

Omeprazole enhanced susceptibility of human tumour cells to 5-fluorouracil

The possibility that PPIs act on the physiological barriers raised by tumour cells to resist to any attack, altering intra- and/or extra-cellular pH, was next investigated. In this experiment, we attempted to verify that this mechanism was effective also in reverting tumour resistance to chemotherapeutic drugs, other than the weak bases. Applying the same experimental design described before, we tested the efficacy of omeprazole on reverting primary tumour cells resistance to 5-fluorouracil (5-FU). This drug is a derivative of uracil and

an analogue of folic acid, and exhibits weak acid characteristics. The effect of omeprazole on cellular resistance to 5-FU was tested on 24 human melanoma, 2 human colon adenocarcinoma and 2 human breast cancer cell lines deriving from primary lesions, and chosen for their resistance to 5FU. Figure 4 shows the results of three representative experiments. A dose response curve was obtained treating cells with 5 different logarithmic dilutions of 5-FU alone, or in the presence of omeprazole and its analogues (not shown). The results clearly showed that 5-fluorouracil sensitivity was restored by pretreating cells with omeprazole. Comparable results were obtained, using the other PPIs, as well as other tumour cell lines (not shown).

The effects of Omeprazole on human cell lines *in vitro* selected for MDR

In order to verify whether alteration of cellular pH could be a mechanism responsible for multidrug resistance as a basal physiological barrier, we tested the effects of omeprazole in cells *in vitro* selected for MDR phenotype and expressing P-glycoprotein as the sole transporter responsible for drug efflux. Particularly, we tested the effects of omeprazole on CEM-VBL100 cells (Figure 5), obtained by selection of the parental human lymphoblastoid CD4+Tcell line CCRF-CEM in a medium containing increasing concentrations of vinblastine sulphate up to 100 ng/ml. CEM-VBL 100 cells express P-glycoprotein and display resistance to 100 ng/ml vinblastine and to other related drugs. Figure 5 shows the results of three representative experiments. A dose response curve was obtained by treating CEM-VBL100 cells with 5 different logarithmic dilutions of vinblastine-sulphate alone or in the presence of omeprazole and its analogues (not shown). The results clearly showed that vinblastine-sulphate sensitivity was restored pretreating cells with omeprazole. Comparable results were obtained by using the other PPIs (not shown), as well as performing the same experiments on the MCF7-DX cell line, obtained by selection of MCF7 parental human breast cancer cell line (not shown).

EXAMPLE 4**IN VIVO DRUGS AND PPIs****MATERIALS AND METHODS*****In vivo experiments***

Cisplatin (Aventis, France) was administered intraperitoneally (i.p.) at a dose of 5 mg/kg (Son and Huang 1994).

Other: unless otherwise specified, other parameters are as set out in Examples 1 and 2, above.

The effects of Omeprazole on sensitivity of human tumours of chemotherapeutic agents as assessed *in vivo* in SCID mice engrafted with human tumour cells.

RESULTS

The *in vitro* experiments had shown a straightforward effect of omeprazole treatment in restoring sensitivity to cytotoxic drugs in human tumour cell lines. However, we needed to test efficacy in *in vivo* systems. To this purpose, we tested the effects of omeprazole and its analogues on a human/mouse model system represented by CB.17 *scid/scid* mice engrafted by subcutaneous (s.c.) injection human melanoma cells. This model has proven useful to test *in vivo* the efficacy of various anti-tumour therapies against human tumours, using either local or systemic treatment strategies (Lozopone 2000, 2002, in press). Mice engrafted with human tumour cells were pre-treated with omeprazole (by gavage) and i.p. with a single dose of cisplatin. The effect of the treatments was measured in terms of tumour growth at different time points. The results (Figure 6) showed that omeprazole pre-treatment markedly increased tumour sensitivity to cisplatin, while cisplatin *per se* did not show a significant effect on tumour growth. The results obtained pretreating mice with omeprazole analogues are fully comparable to that shown with omeprazole (not shown). Once again, histological examination of the human tumours after stopping the experiments showed that, in the tumours from the omeprazole/cisplatin-treated mice, the tumour mass was occupied by a huge necrotic area that mostly accounted for the tumour size (not shown), suggesting that the cytotoxic effect was greater than that quantified by the *in vivo* tumour size measurements.

Treatment strategies

Treatment with anti-tumour drugs, such as cisplatin, might enhance the activity of V-H⁺-ATPase (Murakami T et al 2001). Thus contemporaneous treatment with PPIs and cisplatin, or pre-treatment with cisplatin, might reduce the revertant effect of PPI. Accordingly, we performed experiments in order to assess the possible ineffective combination treatments accounting for a failure of PPI revertant effect. *In vitro* experiments clearly showed that both cisplatin pre-treatment (not shown) and omeprazole-cisplatin co-treatment did not lead to any measurable effect on the viability of human melanoma cells (Fig. 7A). Consistently, *in vivo* co-treatment with cisplatin and omeprazole of melanoma-bearing SCID mice did not show any significant effect on tumour growth (Fig. 7B).
